Abstract

We focus on modeling human activities comprising multiple actions in a completely unsupervised setting. Our model learns the high-level action co-occurrence and temporal relations between the actions in the activity video. We consider the video as a sequence of short-term action clips, called action-words, and an activity is about a set of action-topics indicating which actions are present in the video. Then we propose a new probabilistic model relating the action-words and the action-topics. It allows us to model long-range action relations that commonly exist in the complex activity, which is challenging to capture in the previous works.

We apply our model to unsupervised action segmentation and recognition, and also to a novel application that detects forgotten actions, which we call action patching. For evaluation, we also contribute a new challenging RGB-D activity video dataset recorded by the new Kinect v2, which contains several human daily activities as compositions of multiple actions interacted with different objects. The extensive experiments show the effectiveness of our model.

1. Introduction

We consider modeling human activities containing a sequence of actions (see an example in Fig. 1), as perceived by an RGB-D sensor in home and office environments. In the complex human activity such as warming milk in the example, there are not only short-range action relations, \textit{e.g.}, microwaving is often followed by fetch-bowl-from-oven, but there are also long-range action relations, \textit{e.g.}, fetch-milk-from-fridge is strongly related to put-milk-back-to-fridge even though several other actions occur between them.

The challenge that we undertake in this paper is: Can an algorithm learn about the aforementioned relations in the activities when just given a completely \textit{unlabeled} set of RGB-D videos?

Most previous works focus on action detection in a supervised learning setting. In the training, they are given fully labeled actions in videos \cite{23, 29, 31}, or weakly supervised action labels \cite{9, 7}, or locations of human/their interactive objects \cite{21, 35, 25}. Among them, the temporal structure of actions is often discovered by Markov models such as Hidden Markov Model (HMM) \cite{34} and semi-Markov \cite{12, 32}, or by linear dynamical systems \cite{3}, or by hierarchical grammars \cite{27, 37, 20, 39, 2}, or by other spatio-temporal representations \cite{15, 20, 17, 19}. Most of these works are based on RGB features and only model the short-range relations between actions (see Section 2 for details).

Different from these approaches, we consider a completely unsupervised setting. The novelty of our approach is the ability to model the long-range action relations in the temporal sequence, by considering pairwise action co-occurrence and temporal relations, \textit{e.g.}, put-milk-back-to-fridge often co-occurs with and temporally after fetch-milk-from-fridge. We also use the more informative human skeleton and RGB-D features, which show higher performance over RGB only features for action recognition \cite{18, 42, 22}.
In order to capture the rich structure in the activity, we draw strong parallels with the work done on document modeling from natural language (e.g., [6]). We consider an activity video as a document, which consists of a sequence of short-term action clips as action-words. And an activity is about a set of action-topics indicating which actions are present in the video, such as fetch-milk-from-fridge in the warming milk activity. Action-words are drawn from these action-topics and has a distribution for each topic. Then we model the following (see Fig. 2):

- **Action co-occurrence.** Some actions often co-occur in the same activity. We model the co-occurrence by adding correlated topic priors to the occurrence of action-topics, e.g., fetch-milk-from-fridge and put-milk-back-to-fridge has strong correlations.

- **Action temporal relations.** Some actions often causally follow each other, and actions change over time during the activity execution. We model the relative time distributions between every action-topic pair to capture the temporal relations.

We first show that our model is able to learn meaningful representations from the unlabeled activity videos. We use the model to temporally segment videos to segments assigned with action-topics. We show that these action-topics are semantically meaningful by mapping them to ground-truth action classes and evaluating the labeling performance.

We then also show that our model can be used to detect forgotten actions in the activity, a new application that we call action patching. We show that the learned co-occurrence and temporal relations are very helpful to infer the forgotten actions by evaluating the patching accuracy.

We also provide a new challenging RGB-D activity video dataset recorded by the new Kinect v2 (see examples in Fig. 3), in which the human skeletons and the audio are also recorded. It contains 458 videos of human daily activities as compositions of multiple actions interacted with different objects, in which people forget actions in 222 videos. They are performed by different subjects in different environments with complex backgrounds.

In summary, the main contributions of this work are:

- Our model is completely unsupervised and non-parametric, thus being more useful and scalable.

- Our model considers both the short-range and the long-range action relations, showing the effectiveness in the action segmentation and recognition, as well as in a new application action patching.

- We provide a new challenging RGB-D activity dataset recorded by the new Kinect v2, which contains videos of multiple actions interacted with different objects.

**2. Related Work**

Most previous works on action recognition are supervised [21, 9, 26, 23, 29, 35, 7, 24]. Among them, the linear models [34, 12, 32, 3] are the most popular, which focus on modeling the action transitions in the activities. More complex hierarchical relations [27, 37, 20, 39] or graph relations [2] are considered in modeling actions in the complex activity. Although they have performed well in different areas, most of them rely on local relations between adjacent clips or actions that ignore the long-term action relations.

There also exist some unsupervised approaches on action recognition. Yang et al. [33] develop a meaningful representation by discovering local motion primitives in an unsupervised way, then a HMM is learned over these primitives. Jones et al. [13] propose an unsupervised dual assignment clustering on the dataset recorded from two views.

Different from these approaches, we use the richer human skeleton and RGB-D features rather than the RGB action features [38, 14]. We model the pairwise action co-occurrence and temporal relations in the whole video, thus relations are considered globally and completely with the uncertainty. We also use the learned relations to infer the forgotten actions without any manual annotations.

Action recognition using human skeletons and RGB-D camera have shown the advantages over RGB videos in many works. Skeleton-based approach focus on proposing good skeletal representations [31, 33, 36, 32, 32]. Besides of the human skeletons, we also detect the human interactive objects in an unsupervised way to provide more discriminate features. Object-in-use contextual information has been commonly used for recognizing actions [18, 19, 25, 39]. Most of them depend on correct object tracking or local motion changes. They lost the high-level action relations which can be captured in our model.

Our work is also related to the topic models. LDA [6] was the first hierarchical Bayesian topic model and widely used in different applications. The correlated topic models [1, 16] add the priors over topics to capture topic correlations. A topic model over absolute timestamps of words is proposed in [40] and has been applied to action recognition [10]. However, the independence assumption of different topics would lead to non smooth temporal segmentations. Differently, our model considers both correlations and the relative time distributions between topics rather than the absolute time, which captures richer information of action structures in the complex human activity.

**3. Overview**

We outline our approach in this section (see approach pipeline in Fig. 2). The input to our system is RGB-D videos with the 3D joints of human skeletons from Kinect v2. We first decompose a video into a sequence of overlapping fixed-length temporal clips (step (1)). We then extract the human skeleton features and the human interactive object features from the clips (introduced in Section. 3.1), which show higher performance over RGB only features for action recognition [18, 42, 22].
In order to build a compact representation of the action video, we draw parallels to document modeling in the natural language [6] to represent a video as a sequence of words. We use k-means to cluster the clips to form an action-dictionary, where we use the cluster centers as action-words (step (2)). Then, the video can be represented as a sequence of action-word indices by mapping its clips to the nearest action-words in the dictionary (step (3)). And an activity video is about a set of action-topics indicating which actions are present in the video.

The unsupervised action-topic assignments of action-words are challenging because there is no annotations during the training stage. Besides extracting rich visual features, we consider the relations between action-topics. Using the learned model, we can assign the action-topic to each clip (step (5)), so that we can get the action segments, the continuous clips with the same assigned topic.

The unsupervised action-topic assignments of action-words are challenging because there is no annotations during the training stage. Besides extracting rich visual features, we consider the relations between action-topics. Using the learned model, we can assign the action-topic to each clip (step (5)), so that we can get the action segments, the continuous clips with the same assigned topic.

### 3.1. Visual Features

We describe how we extract the visual features of a clip in this sub-section. We extract both skeleton and object features from the output by the Kinect v2 [1], which has an improved body tracker and higher resolution of RGB-D frame than the Kinect v1. The skeleton has 25 joints in total. Let $X_c = \{x_1^c, x_2^c, \ldots, x_{25}^c\}$ be the 3D coordinates of 25 joints of a skeleton in the current frame. We first compute the cosine of the angles between the connected parts in each frame: $\alpha_i = p_{i+1} \cdot p_i/|p_{i+1}| \cdot |p_i|$, where $p_i = x_{i+1} - x_i$ is the body part. The change of the joint coordinates and angles can well capture the human body movements. So we extract the motion features and off-set features [42] by computing their Euclidean distances $\mathcal{D}(\cdot, \cdot)$ to previous frame $f_{c,c-1}^z, f_{c,c-1}^\alpha$ and the first frame $f_{c,1}^z, f_{c,1}^\alpha$ in the clip:

$$
\begin{align*}
    f_{c,c-1}^z &= \{\mathcal{D}(x_1^c, x_{c-1}^z)\}_{i=1}^{25}, \quad f_{c,c-1}^\alpha = \{\mathcal{D}(\alpha_i^c, \alpha_{c-1}^\alpha)\}_{i=1}^{25}, \\
    f_{c,1}^z &= \{\mathcal{D}(x_1^c, x_1^z)\}_{i=1}^{25}, \quad f_{c,1}^\alpha = \{\mathcal{D}(\alpha_1^c, \alpha_1^\alpha)\}_{i=1}^{25}.
\end{align*}
$$

Then we concatenate all $f_{c,c-1}^z, f_{c,c-1}^\alpha, f_{c,1}^z, f_{c,1}^\alpha$ as the human features of the clip.

We also extract the human interactive objects based on the human hands, motion detection and edge detection. The interactive objects can help discriminate the different human actions with similar body motions such as fetch-book and turn-on-monitor. To detect the interactive objects, first we segment each frame into super-pixels using a fast edge detection approach [9] on both RGB and depth images. The image segmentation provides richer candidate super-pixels...
rather than pixels to further extracting objects. Second we use a moving targets detection approach [28] to detecting foreground mask by removing the unnecessary steady backgrounds. Third we consider the interactive objects should be close to tracked human hands. Combining above three facts, we extract features from the image segments with more than 50% in the foreground mask and within a distance to the human hand joints in both 3D points and 2D pixels (see examples in Fig. 3). Then we extract six kernel descriptors from these image segments: gradient, color, local binary pattern, depth gradient, spin, surface normals, and KPCA/self-similarity, which have been proven to be useful features for RGB-D scene labeling [41]. We concatenate the human features and the object features as the final feature vector of a clip.

4. Learning Model

In order to incorporate the aforementioned properties of activities for patching, we present a new generative model (see the graphic model in Fig. 4 right and the notations in Fig. 5 and Table 1). The novelty of our model is the ability to infer the probability of forgotten actions in a complex activity video.

Consider a collection of $D$ videos (documents in the topic model). Each video consists of $N_d$ action-words \{\(w_{nd}\)\}_{n=1}^{N_d}$ mapped to the action-dictionary. Consider $K$ latent action-topics, \(z_{nd}\) is the topic assignment of each word, indicating which action-topic the action-word \(w_{nd}\) belongs to in the video. Then continuous action-words with the same topic in a video consist an action segment, and the segments assigned with the same topic from different videos consist an action-topic segment cluster.

The topic model such as LDA [6] has been very common for document modeling from language (see graphic model in Fig. 4 left), which generates a document using a mixture of topics. To model human actions in the video, our model introduces co-occurrence and temporal structure of topics instead of the topic independency assumption in LDA.

</tbody>
</table>

**Basic generative process.** In a document \(d\), the topic assignment \(z_{nd}\) is chosen from a multinomial distribution with parameter \(\pi_d\), \(z_{nd} \sim \text{Mult}(\pi_d)\), where \(\pi_d\) is sampled from a prior. And the word \(w_{nd}\) is generated by a topic-specific multinomial distribution \(\phi_{z_{nd}}\), \(w_{nd} \sim \text{Mult}(\phi_{z_{nd}})\), where \(\phi_k \sim \text{Dir}(\beta)\) is the word distribution of topic \(k\), sampled from a Dirichlet prior with the hyperparameter \(\beta\).

**Topic correlations.** First we consider correlations between topics to model the probabilities of co-occurrence of actions. Let \(\pi_{kd}\) be the probability of topic \(k\) occurring in document \(d\), where \(\sum_{k=1}^{K} \pi_{kd} = 1\). Instead of sampling it from a fix Dirichlet prior with parameter \(\alpha\) in LDA, we construct the probabilities by a stick-breaking process:

\[
\pi_{kd} = \Psi(v_{kd}) \prod_{l=1}^{k-1} \Psi(v_{ld}), \quad \Psi(v_{kd}) = \frac{1}{1 + \exp(-v_{kd})},
\]

where \(0 < \Psi(v_{kd}) < 1\) is a classic logistic function, which satisfies \(\Psi(-v_{kd}) = 1 - \Psi(v_{kd})\), and \(v_{kd}\) serves as the prior of \(\pi_{kd}\).

**Relative time distributions.** Second we model the relative time of occurring actions by taking their time stamps into account. We consider that the relative time between two words are drawn from a certain distribution according to their topic assignments. In detail, let \(t_{nd}, t_{md} \in (0, 1)\) be the absolute time stamp of \(n\)-th word and \(m\)-th word, which is normalized by the video length. \(t_{mnd} = t_{md} - t_{nd}\) is the relative time of \(m\)-th word relative to \(n\)-th word (the green line in Fig. 5). Then \(t_{mnd}\) is drawn from a certain distribution, \(t_{mnd} \sim \Omega(\theta_{z_{mnd}, z_{nd}})\), where \(\theta_{z_{mnd}, z_{nd}}\) are the parameters. \(\Omega(\theta_{k,l})\) are \(K^2\) pairwise topic-specific relative
time distributions defined as follows:

\[
\Omega(t|\theta_{k,l}) = \begin{cases} 
    b_{k,l} \cdot N(t|\theta_{k,l}^+) & \text{if } t \geq 0, \\
    1 - b_{k,l} \cdot N(t|\theta_{k,l}^-) & \text{if } t < 0,
\end{cases}
\]  

(1)

An illustration of the learned relative time distributions are shown in Fig. 6. We can see that the distributions we learned can correctly reflect the order of the actions, e.g., put-back-to-fridge is after pouring and can be before/after microwaving, and the shape is mostly similar to the real distributions. Here the Bernoulli distribution \( b_{k,l} = 1/\{1 + e^t \} \) gives the probability of action \( k \) after/before the action \( l \). And two independent normal distributions \( N(t|\theta_{k,l}^+), N(t|\theta_{k,l}^-) \) estimate how long the action \( k \) is after/before the action \( l \). Then the order and the length of the actions will be captured by all these pairwise relative time distributions.

5. Gibbs Sampling for Learning and Inference

Gibbs sampling is commonly used as a means of statistical inference to approximate the distributions of variables when direct sampling is difficult. Given a video, the word \( w_{n,d} \) and the relative time \( t_{n,m,d} \) are observed. In the training stage, given a set of training videos, we use Gibbs sampling to approximately sample other hidden variables from the posterior distribution of our model. Since we adopt conjugate prior \( \text{Dir}(\beta) \) for the multinomial distributions \( \Phi_k \), we can easily integrate out \( \Phi_k \) and need not to sample them. For simplicity and efficiency, we estimate the standard distributions including the multivariate normal distribution \( N(\mu, \Sigma) \) and the time distribution \( \Omega(\theta_{d}) \) by the method of moments, once per iteration of Gibbs sampling. And as in many applications using the topic model, we use fixed symmetric Dirichlet distributions by setting \( \beta = 0.01 \).

In the Gibbs sampling updates, then we need to sample the topic assignment \( z_{n,d} \) and the topic prior \( \nu_{v,d} \). We can do a collapsed sampling as in LDA by calculating the posterior distribution of \( z_{n,d} \):

\[
p(z_{n,d} = k | \pi_{d}, z_{-n,d}, t_{n,d}) \propto \pi_{kd} \omega(k, w_{n,d}) p(t_{n,d} | z_{n,d}; \theta),
\]

\[
\omega(k, w_{n,d}) = \frac{N_{kw} + \beta}{N_{k}^{-nd} + N \beta},
\]

(2)

\[
p(t_{n,d} | z_{n,d}; \theta) = \prod_{m} \Omega(t_{mn,d} | \theta_{z_{n,d}, k}) \Omega(t_{n,m,d} | \theta_{z_{n,d}, k}),
\]

where \( \pi_{k} \) is the number of unique word types in dictionary, \( N_{kw} \) denotes the number of instances of word \( w_{n,d} \) assigned with topic \( k \), excluding \( n \)-th word in \( d \)-th document, and \( N_{k}^{-nd} \) denotes the number of total words assigned with topic \( k \). \( z_{-n,d} \) denotes the topic assignments for all words except \( z_{n,d} \).

Note that, in Eq. (2), \( \pi_{kd} \) is the topic prior generated by a joint distribution giving which actions are more likely to co-occur in the video. \( \omega(k, w_{n,d}) \) is the word distribution for topic \( k \) giving which topic the word is more likely from. And \( p(t_{n,d} | z_{n,d}; \theta) \) is the time distribution giving which topic-assignment of the word is more causally consistent to other topic-assignments.

Due to the logistic stick-breaking transformation, the posterior distribution of \( \nu_{v,d} \) does not have a closed form. So we instead use a Metropolis-Hastings independence sampler. Let the proposals \( q(v_{n,d}^{*} | v_{n,d}, \mu, \Sigma) = N(v_{n,d}^{*} | \mu, \Sigma) \) be drawn from the prior. The proposal is accepted with probability \( \min(A(v_{n,d}^{*}, v_{n,d}), 1) \), where

\[
A(v_{n,d}^{*}, v_{n,d}) = \frac{\sum_{k=1}^{K} \pi_{kd} \delta(z_{n,d}, k)}{\sum_{k=1}^{K} \pi_{kd} \delta(z_{n,d}, k)},
\]

which can be easily calculated by counting the number of words assigned with each topic by \( z_{n,d} \). Here the function \( \delta(x, y) = 1 \) if only if \( x = y \), otherwise equal to 0. The time complexity of the sampling per iteration is \( O(N_{d}^{2}KD) \).

Given a test video, we fix all parameters learned in the training stage and only sample the topic assignments \( z_{n,d} \) and the topic priors \( \nu_{v,d} \).

5.1. Action Segmentation and Recognition

After we learn the topic-assignment of each action-word, we can easily get the action segments by merging the continuous clips with the same assigned topic. Also the assigned topic of the segment indicate which action it is and these segments with the same assigned topic consist an action-topic segment cluster.

5.2. Action Patching

We also apply our model in a new significant application, called action patching. It reminds people of forgotten actions by output a segment containing the forgotten action from the training set (illustrated in Fig. 5). It is more challenging than conventional similarity search, since the
retrieved target is not shown in the query video. Therefore, learning the action co-occurrence and the temporal relations is important in this application.

Different from existing models on action relations learning, our model learns all the pairwise relations rather than only the local and the past-to-future transitions. This is very useful to patching, since those actions occurred with a relatively large time interval with or actions occurred after the forgotten actions are also helpful to detect it, e.g., *put-back-book* might be forgotten as previously seen a *fetch-book* action before a long reading, and seen a leaving action indicates he really forgot to *put-back-book*.

Our model infers the forgotten action using the probability inference based on the dependencies. After assigning the topics to the action-words of a query video $q$, we consider adding one additional action-word $\hat{w}$ into the video in each segmentation point $t_s$. Then the probabilities of the missing topics $k_m$ in each segmentation point can be compared following the posterior distribution in Eq. (1):

$$p(z_{t_s} = k_m, t_s = t_{\text{other}}) \propto \pi_{k_m} d_p(t_s|z_d, \theta) \sum_w \omega(k_m, w),$$

s.t. $t_s \in T_s$, $k_m \in [1 : K] - K_e$,

where $T_s$ is the set of segmentation points ($t_1$, $t_2$ in Fig. 7) and $K_e$ is the set of existing topics in the video (*fetch-book*, etc. in Fig. 7). Thus $[1 : K] - K_e$ are the missing topics in the video (*turn-off-monitor*, etc. in Fig. 7). $p(t_s|z_d, \theta), \omega(k_m, w)$ can be computed as in Eq. (2). Here we marginalized $\hat{w}$ to avoid the effect of a specific action-word. Note that, $\pi_{kd}$ gives the probability of a missing topic in the video decided by the correlation we learned in the joint distribution prior, i.e., the close topics have higher probabilities to occur in this query video. And $p(t_s|z_d, \theta)$ measures the casual consistency of adding a new topic.

Then we rank the pair $(k_m, t_s)$ using the above score and select the top ones (three in the experiments). The segments with the selected topics $k_m$ in the training set consist a candidate patching segment set. Finally, we select the top one from the candidates to output by comparing their frame-wise distances. In detail, we consider that the front and the tail of the patching segment $f_{pt}$ should be similar to the tail of the adjacent segment in $q$ before $t_s$ and the front of the adjacent segment in $q$ after $t_s$: $f_{qt}$, $f_{qt}$. At the same time, the middle of the patching segment $f_{pm}$ should be different to $f_{qt}$, $f_{qt}$, as it is a different action forgotten in the video. So we choose the patching segment with the maximum score: $\text{ave}(\mathbb{D}(f_{pm}, f_{qt})) - \text{max}(\mathbb{D}(f_{pf}, f_{qt}), \mathbb{D}(f_{pt}, f_{qt}))$, where $\mathbb{D}(\cdot)$ is the average pairwise distances between frames, $\text{ave}(\cdot)$, $\text{max}(\cdot)$ are the average and max value. If the maximum score is below a threshold or there is no missing topics (i.e., $K_e = [1 : K]$) in the query video, we claim there is no forgotten actions.

6. Experiments

6.1. Dataset

We collect a new challenging RGB-D activity dataset recorded by the new Kinect v2 camera\(^2\). Each video in the dataset contains 2-7 actions interacted with different objects (see examples in Fig. 8). The new Kinect v2 has higher resolution of RGB-D frames (RGB: $1920 \times 1080$, depth: $512 \times 424$) and improved body tracking of human skeletons (25 body joints). We record 458 videos with a total length of about 230 minutes. We ask 7 subjects to perform human daily activities in 8 offices and 5 kitchens with complex backgrounds. And in each environment the activities are recorded in different views. It composed of fully annotated 21 types of actions (10 in the office, 11 in the kitchen) interacted with 23 types of objects. We also record the audio, though it is not used in this paper.

In order to get a variation in activities, we ask participants to finish task with different combinations of actions and ordering naturally. Some actions occur together often such as *fetch-from-fridge* and *put-back-to-fridge* while some are not always in the same video (see more examples on our website). Some actions are in fix ordering such as *fetch-book* and *put-back-book* while some occur in random order. Moreover, to evaluate the action patching performance, 222 videos in the dataset has action forgotten by people naturally and the forgotten actions are annotated.

6.2. Experimental Setting and Compared Baselines

We evaluate in two environments ‘office’ and ‘kitchen’. In each environment, we split the data into a train set with most full videos (office: 87, kitchen 119) and a few forgotten videos (office: 10, kitchen 10), and a test set with a few full videos (office: 10, kitchen 20) and most forgotten videos (office: 89, kitchen 113). We compare seven unsupervised approaches in our experiments. They are Hidden

\(^2\)The dataset and tools are released at [http://watchnpatch.cs.cornell.edu](http://watchnpatch.cs.cornell.edu)
Markov Model (HMM), topic model LDA (TM), correlated topic model (CTM), topic model over absolute time (TM-AT), correlated topic model over absolute time (CTM-AT), topic model over relative time (TM-RT) and our causal topic model (CaTM), that is the correlated topic model over relative time. All these methods use the same human skeleton and RGB-D features introduced in Section 3.1. We also evaluate HMM and our model CaTM using the popular features for action recognition, dense trajectories feature (DTF) [38], extracted only in RGB videos named as HMM-DTF and CaTM-DTF.

In the experiments, we set the number of topics (states of HMM) equal to or more than ground-truth action classes. For correlated topic models, we use the same topic prior in our model. For models over absolute time, we consider the absolute time of each word is drawn from a topic-specific normal distribution. For models over relative time, we use the same relative time distribution as in our model (Eq. (1)). The clip length of the action-words is set to 20 frames, densely sampled by step one and the size of action dictionary is set to 500. For patching, the candidate set for different approaches consist of the segments with the inferred missing topics by transition probabilities for HMM, the topic priors for TM and CTM, and both the topic priors and the time distributions for TM-AT, TM-RT, CTM-AT and our CaTM. Then we use the same ranking score as in Section 5.2 to select the top one patched segments.

6.3. Evaluation Metrics

We want to evaluate if the unsupervised learned action-topics (states for HMM) are semantically meaningful. We first map the assigned topics to the ground-truth labels for evaluation. This could be done by counting the mapped frames between topics and ground-truth classes. Let \( k_i, c_i \) be the assigned topic and ground-truth class of frame \( i \). The count of a mapping is: \( m_{kc} = \frac{\sum_i \delta(k_i, k) \delta(c_i, c)}{\sum_i \delta(c_i, c)} \), where \( \sum_i \delta(k_i, k) \delta(c_i, c) \) is the number of frames assigned with topic \( k \) as the ground-truth class \( c \) and normalized by the number of frames as the ground-truth class \( c: \sum_i \delta(c_i, c) \). Then we can solve the following binary linear programming to get the best mapping:

\[
\max_x \sum_{k,c} x_{kc} m_{kc},
\]

s.t. \( \forall k, \sum_c x_{kc} = 1, \forall c, \sum_k x_{kc} \geq 1, x_{kc} \in \{0, 1\}, \)

where \( x_{kc} = 1 \) indicates mapping topic \( k \) to class \( c \), otherwise \( x_{kc} = 0 \). And \( \sum_c x_{kc} = 1 \) constrain that each topic must be mapped to exact one class. \( \sum_k x_{kc} \geq 1 \) constrain that each class must be mapped by at least one topic.

We then measure the performance in two ways. Per frame: we compute frame-wise accuracy (Frame-Acc), the ratio of correctly labeled frames. Segmentation: we consider a true positive if the overlap (union/intersection) between the detected and the ground-truth segments is more than a default threshold 40% as in [27]. Then we compute segmentation accuracy (Seg-Acc), the ratio of the ground-truth segments that are correctly detected, and segmentation average precision (Seg-AP) by sorting all action segments output by the approach using the average probability of their words’ topic assignments. All above three metrics are computed by taking the average of each action class.

We also evaluate the patching accuracy (P-Acc) by the portion of correct patched video, including correctly output the forgotten action segments or correctly claiming no forgotten actions. We consider the output action segments by the algorithm containing over 50% ground-truth forgotten actions as correctly output the forgotten action segments.

6.4. Results

Table 2 and Fig. 9 show the main results of our experiments. We first perform evaluation in the offline setting to see if actions can be well segmented and clustered in the train set. We then perform testing in an online setting to see if the new video from the test set can be correctly segmented and the segments can be correctly assigned to the action cluster. We can see that our approach performs better than the state-of-the-art in unsupervised action segmentation and recognition, as well as action patching. We discuss our results in the light of the following questions.

Did modeling the long-range relations help? We studied whether modeling the correlations and the temporal relations between topics was useful. The approaches considering the temporal relations, HMM, TM-RT, and our CaTM, outperform other approaches which assume actions are temporal independent. This demonstrates that understanding temporal structure is critical to recognizing and patching actions. The approaches, TM-RT and CaTM, which model both the short-range and the long-range relations perform better than HMM only modeling local relations. Also, the approaches considering the topic correlations CTM, CTM-AT, and our CaTM perform better than the corresponding non-correlated topic models TM, TM-AT, and TM-RT. Our CaTM, which considers both the action correlation priors
Table 2: Results using the same number of topics as the ground-truth action classes. HMM-DTF, CaTM-DTF use DTF RGB features and others use our human skeleton and RGB-D features.

Figure 9: Online segmentation Acc/AP varied with the number of topics in ‘office’ dataset.

and the temporal relations, shows the best performance.

How successful was our unsupervised approach in learning meaningful action-topics? From Table 2 we can see that the unsupervised learned action-topics can be semantically meaningful even though ground-truth semantic labels are not provided in the training. In order to qualitatively estimate the performance, we give a visualization of our learned topics in Fig. 10. It shows that the actions with the same semantic meaning are clustered together though they are in different views and motions. In addition to the one-to-one correspondence between topics and semantic action classes, we also plot the performance curves varied with the topic number in Fig. 9. It shows that if we set the topics a bit more than ground-truth classes, the performance increases since a certain action might be divided into multiple action-topics. But as topics increase, more variations are also introduced so that performance saturates.

RGB videos vs. RGB-D videos. In order to compare the effect of using information from RGB-D videos, we also evaluate our model CaTM and HMM using the popular RGB features for action recognition (CaTM-DTF and HMM-DTF in Table 2). Clearly, the proposed human skeleton and RGB-D features outperform the DTF features as more accurate human motion and object are extracted.

How well did our new application of action patching performs? From Table 2 we find that the approaches learning the action relations mostly give better patching performance. This is because the learned co-occurrence and temporal structure strongly help indicate which actions are forgotten. Our model capturing both the short-range and long-range action relations shows the best results.

6.5. Sharing the Learned Topics
In order to make our learned knowledge useful to robots, we also share the learned topics to RoboBrain [30], a large-scale knowledge engine for robots. Our learned action topics are represented as nodes in the knowledge graph for robots and these nodes are connected with edges of our learned co-occurrence and temporal relations.

7. Conclusion
In this paper, we presented an algorithm that models the human activities in a completely unsupervised setting. We showed that it is important to model the long-range relations between the actions. To achieve this, we considered the video as a sequence of action-words, and an activity as a set of action-topics. Then we modeled the word-topic distributions, the topic correlations and the topic relative time distributions. We then showed the effectiveness of our model in the unsupervised action segmentation and recognition, as well as the action patching. For evaluation, we also contributed a new challenging RGB-D activity video dataset.
